

OXIDE BASED CERAMIC MATRIX COMPOSITES

TECHNICAL FIELD

[0001] The present invention generally relates to ceramic matrix composites and particularly to oxide-based ceramic matrix composites comprising sol gel and the processes for making such composites.

BACKGROUND OF THE INVENTION

[0002] Ceramic Matrix Composite (CMC) is an emerging material well suited to high temperature structural environments for aerospace and industrial applications. Advanced structural ceramics are materials that have relatively high mechanical strength at high temperatures. These materials face a number of physically demanding conditions such as high temperature, corrosive conditions, and high acoustic environments.

[0003] The oxide based ceramic matrix composites (CMC) developed are economic, low dielectric, thermally stable, structural ceramic systems stable to at least 2300 °F. The matrix is reinforceable with a variety of fibers (Quartz, Nextel 312, 550, 619, 650, 720). Preferably the fiber is, but not limited to, Nextel 720. The CMC's primary advantage over carbon-carbon and other high temperature composites is its low cost and near net-shape manufacturing process.

[0004] Prior to 1980 ceramics were considered monolithic, being made of one material. The advantages of monolithic ceramics is that the ceramic

properties such as high strength, wear resistance, hardness, stiffness, corrosion resistance, thermal expansion and density can be varied depending on the starting materials. However the density of the monolithic ceramics are significantly lower ($0.08 - 0.14 \text{ lb/in}^3$) compared to metallic counterparts (generally $> 0.3 \text{ lb/in}^3$). Also, these ceramics are not ductile like metal, and instead may shatter, crack or crumble under applied stress and/or strain. Therefore, physical properties prevented designers from considering ceramics in many structural applications.

[0005] In the mid-1980s a revolution in the field of ceramics occurred with the development of new ceramic fibers (from Nippon Carbon and 3M) and the development of the Chemical Vapor Infiltration process (CVI). Fibers added to a ceramic matrix produce a fiber-reinforced ceramic, which increases the ceramic strength and toughness and eliminates or reduces the likelihood of poor operational results at high temperatures. Each unique type of fiber added to the ceramic mix provides unique properties to the material. The exploration of fiber types and resulting properties led to numerous combinations uniquely tailored to specific ceramic applications. These ceramics are known as ceramic matrix composite (CMC) or continuous-fiber-reinforced ceramic composites (CFCC) which distinguish them from chopped fiber reinforced ceramics.

[0006] The key to the strength and toughness of a CMC system is to maintain a limited amount of fiber matrix bonding. This is difficult to achieve considering the amount of thermal energy that is being applied to the surface

chemistry of the matrix and fiber surface. Success exists in four basic types of ceramic matrix systems: (1) Chemical vapor infiltration (CVI), (2) glass ceramics, (3) organo-metallic derived from polymer precursors, and (4) oxide matrix ceramics.

[0007] As discussed above, CMC produced using the CVI process overcomes the drawbacks of monolithic ceramics. However, major drawbacks of infiltrating the fabric using the CVI process are the expense and time required to produce parts, which in particular instances, requires months. Further, the process is labor and capital intensive, and limited with respect to the size and shape of parts that can be produced.

[0008] More recently, a number of CMC organic-metallic processes have been developed. These processes follow the same standard processing procedures and equipment developed for making organic composites, thereby eliminating many of the slow and costly limitations that were found with the CVI process. In the CMC processes ceramic fibers are first made and woven into cloths, such as fiberglass or carbon fiber for organic composites. The flexible ceramic cloth is then infiltrated with an organic-metallic matrix such as an epoxy matrix for organic composites. This impregnated cloth is then placed on a complex tool and processed under low pressure and low temperature in a process known as autoclaving. After autoclaving, a complex shaped ceramic structure is formed and then further heated in a furnace to finish the process.

[0009] Glass ceramic CMC formation typically begins with a glass powder, often formulated with silicates that are thermoplastically formed along

with reinforcing fibers at very high temperatures and pressures. The fibers require protection with fiber interface coatings such as boron nitride (BN) in order to control fiber matrix interface. The glass ceramic CMC is subjected to a free standing post cure to crystallize the matrix. Fiber interface coatings are susceptible to oxidation well below 1800 °F. However, in a high-densified system such as this, the fiber coatings are protected from the oxidizing environment. High strengths are achievable with flat panels, however the inability to manufacture complex shapes greatly restricts the application glass ceramics.

[0010] Organo-metallic ceramics derived from polymer precursors are analogous to carbon-carbon ceramic matrices. A polymer composite is fabricated and then pyrolyzed to a ceramic. The volume loss during pyrolysis must be reinfiltrated with resin and pyrolyzed again. This process may be repeated up to ten times in order to achieve the densification necessary to provide oxidation protection to fiber coatings. The most common organo-metallic systems are Polysiazane and Blackglas (Allied Signal). Silicon carbide (SiC) fibers such as Nicalon by Dow Corning are most commonly used with this system, along with fiber coating such as boron nitride (BN). The disadvantages to this system are the high cost, high dielectric constant and the susceptibility of the BN coatings to oxidation. The non-oxide CMC systems require the BN interface with a dense matrix. High strengths are achievable, but the limitation of the material lies in the stress at which the matrix begins to crack (typically about 10 ksi) and also when the BN fiber interface coating begins to oxidize. Stress cracking also becomes evident during cyclical loading of the material.

[0011] In recent years, efforts have been made to manufacture oxide matrix ceramics capable of withstanding temperatures greater than 2000 °F. One such matrix developed was the aluminum phosphate bonded alumina oxide CMC. Fiber reinforcement was primary Nicalon 8 harness satin fabric. However, studies of the matrix found repetitive cycles in excess of 1500 °F caused phase inversions in the matrix limiting use of the material to a temperature no greater than 1400 °F.

SUMMARY OF THE INVENTION

[0012] The present invention provides ceramic matrix composites (CMC) having superior properties at high temperatures. In one embodiment, the CMC comprises a sol gel matrix with alumina powder mixed or blended into the matrix. The sol-gel matrix is an aqueous colloidal suspension of a metal oxide, preferably composed of particles in the size range of 4-150 nanometers and concentrations from about 10 wt% to about 25 wt% of the metal oxide. Preferably the metal oxide is alumina (Al_2O_3), silica (SiO_2) or alumina-coated silica.

[0013] Methods for making the CMC of the present invention are also provided. The methods of the present invention comprise providing a sol-gel matrix and mixing or blending alumina powder into the matrix. The alumina powder preferably comprises from about 30 wt% to about 60 wt% of the blended mixture. In a preferred embodiment, the alumina powder that is mixed into the sol has a size less than or equal to about 1.5 microns and preferably from about

0.1 microns to about 1.0 microns. If necessary, the pH of the mixture is adjusted to prevent gelling by adding acid or base to the mixture. The sol-gel mixture is then ball milled or high shear mixed to remove any soft agglomerates that form, producing a homogeneous suspension. In a further embodiment, this homogeneous solution is then infiltrated using a doctor blade casting set up into a suitable ceramic cloth or fabric. Layers of infiltrated fabrics are laid up and placed in a vacuum bag, cured with or without pressure from a press or autoclave, then de-bagged and fired.

[0014] In another embodiment, complex parts can be manufactured using the CMC of the present invention in a similar processing procedure for organic composites. Layers of infiltrated fabric are slightly dried to develop tack, draped over the desired tool form, then subjected to a vacuum bag cure and/or autoclave cured to 350 °F. The tool form is then removed and the part is post cured at a temperature from about 1000 °F to about 2300 °F, preferably 2000 °F.

[0015] One of the objects of the present invention is to manufacture a ceramic matrix that can withstand high temperature and has a high strength including porosity for toughness. It is another object of the present invention to manufacture a ceramic matrix composite that is alcohol, or preferably, water based.

[0016] Further areas of applicability of the present invention will become apparent from the detailed description provided hereinafter. It should be understood that the detailed description and examples, while indicating preferred embodiments of the invention, are intended for purposes of illustration only, since

various changes and modifications within the spirit and scope of the invention will become apparent to those skilled in the art from this detailed description.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

[0017] In accordance with the broad teachings of the present invention, a ceramic matrix composite is manufactured using a sol gel matrix mixture comprising a sol-gel matrix and alumina powder. The mixture can also contain polymers (acrylic polymers) to improve processing, but the polymer is not necessary. The mixture is then infiltrated into a suitable ceramic cloth or fabric to obtain a fiber reinforced ceramic matrix composite (CMC) that is suitable for manufacturing a number of complex shape tools.

[0018] In one embodiment, the ceramic matrix composition comprises a sol-gel and alumina powder. In a preferred embodiment, the sol-gel is from about 40 wt% to about 70 wt% of the sol-gel and alumina mixture. Sol-gel is a material that can be used for making advanced materials including ceramics. There are two phases to the material, a liquid "sol", which is a colloidal suspension, and a solid "gel" phase. The transition from the liquid sol phase to the solid gel phase can be triggered by drying, heat treatment or increasing the pH to the basic range. The starting materials used in the preparation of the sol-gel are usually inorganic metal salts or metal organic compounds such as metal alkoxides. In a preferred embodiment of the present invention, the sol-gel comprises metal oxides, preferably alumina (Al_2O_3), silica (SiO_2) or alumina-coated silica and more preferably, alumina. In another preferred embodiment,

the sol-gel comprises from about 10 wt% to about 25 wt% of the metal oxide. Sol-gels are commercially available (from Nalco Chemical or Vista Chemical Company) or can be made by methods known to those skilled in the art.

[0019] In another embodiment, the ceramic matrix composite comprises alumina powder blended with or mixed into the sol gel to produce a sol-gel and alumina mixture. In a preferred embodiment, the alumina is from about 30 wt% to about 60 wt% of the mixture. In another preferred embodiment, the alumina powder particles have a size of less than 1.5 microns. Preferably the alumina powder particles have a size less than 1 micron and more preferably from about 0.1 microns to about 1.5 microns. A smaller particle size will result in better infiltration of the sol-gel and alumina powder mixture into a ceramic cloth or fabric to form a CMC. Another advantage of a smaller particle size is improved bonding and sintering of the CMC. The fine particles bond at just 350 °F allowing for the fabrication of complex shaped parts using low cost tooling, at which point the parts are rigid and tooling can be removed. Parts can then be fired tool free from 1000 °F to 2300 °F, inclusive. This low firing or sintering temperature also does little damage to fiber in the CMC, providing maximum composite strength.

[0020] The mixture composition determines the CMC properties of the present invention. An increasing ratio (by weight) of alumina to silica provides a CMC with superior high temperature refractory properties. For example, a mixture having 100% alumina will have the best refractory properties. However, the addition of silica provides the CMC with additional strength.

Therefore, in a preferred embodiment, the amount of silica in the sol-gel and alumina mixture is from about 0 wt% to about 10 wt%. In a more preferred embodiment, silica comprises no more than approximately one third of the sol-gel mixture. When silica is mixed with alumina sol it is preferred to use the alumina coated silica sol since the pH of the two sols are similar and premature gelling of the two sols is prevented.

[0021] The present invention also provides a method for producing a complex matrix composite, comprising the steps of blending or mixing alumina powder into a sol-gel matrix, treating the matrix to produce a homogeneous suspension and infiltrating a ceramic cloth or fabric with the sol-gel and alumina mixture. In one embodiment, alumina powder is blended with or mixed into the sol-gel matrix. Preferably the amount of alumina is from about 30 wt% to about 60 wt%. The addition of alumina powder to the sol-gel matrix results in a mixture that is highly loaded with solids and yet has low viscosity.

[0022] In another embodiment, the pH of the sol-gel mixture is adjusted to neutral pH, if necessary. For example, addition of the alumina to the sol-gel matrix can result in a mixture that is more alkaline. This change in pH may trigger the undesired transition between the liquid "sol" into the solid "gel". To prevent this, acid may be added to balance the pH of the mixture. In a preferred embodiment, the amount of acid added to the mixture is from about 0.1 wt% to about 0.3 wt% and more preferably about 0.1 wt%. Suitable acids include, but are not limited to, nitric acid, hydrochloric acid, acetic acid or sulfuric acid. In a preferred embodiment, the acid is nitric acid.

[0023]

[0024]

and the volatile components are removed. The sol-gel and alumina mixture bonds the alumina powder and the ceramic fiber assembly at just 350 °F. The parameters of gelling and drying steps are dependent upon many factors including the dimensions of the tool. In a further embodiment, the steps of infiltrating, gelling and drying can be repeated to achieve the desired density of the CMC.

[0025] In another embodiment, the tools are removed after 350 °F cure and then dried, so the infiltrated fabric retains the desired shape. The infiltrated fabric is then densified fully by sintering it at approximately 2000 °F while free standing without tools. Sintering involves heating the infiltrated fabric to react the dried sol-gel with alumina powder mixture. This gives the CMC load bearing strength.

[0026] The foregoing and other aspects of the invention may be better understood in connection with the following examples, which are presented for purposes of illustration and not by way of limitation.

EXAMPLE 1

100% Alumina Ceramic Matrix

[0027] Alumina Sol (14N-4-25, Vista Chemicals) containing 25% solids of colloidal alumina (Al_2O_3) in water was mixed in a blender with submicron alumina powder (SM-8, Baikowski). The matrix contained 57 wt% of alumina sol and 43 wt% of alumina powder. Several drops of nitric acid (about 0.1%) were

added to the matrix to balance the pH. The matrix was then ball milled with alumina media for 4 hours before infiltrating into the fabric.

[0028] The matrix mixture was infiltrated into the fabric using a doctor blade or a pinched roller set up. This allowed the matrix to fully infiltrate into the fabric. After fabric infiltration, the matrix was slightly dried to develop tack. The material was then draped on complex tools, vacuum bagged having standard bleeders and breathers used in the organic composite industry and autoclaved to 350 °F. After exposing the matrix to heat to set the matrix, the vacuum bag and tools were removed. The resulting part was post cured free standing between 1500 °F and 2300 °F, preferably 2000 °F.

EXAMPLE 2

Alumina/Silica Ceramic Matrix

[0029] Alumina-coated Silica Sol (1056, Nalco Chemicals) containing 20% solids of colloidal silica (SiO_2) coated with alumina (Al_2O_3) in water was mixed in a blender with submicron alumina powder (SM-8, Baikowski). The matrix contained 57 wt% of alumina-coated silica sol and 43 wt% of alumina powder. Several drops of nitric acid (about 0.1%) were added to the matrix to balance the pH. The matrix was then ball milled with alumina media for 4 hours before infiltrating into the fabric. The fabric was infiltrated by the same method as described in Example 1.

EXAMPLE 3

Alumina/Silica Ceramic Matrix

[0030] Silica Sol (2327, Nalco Chemicals) containing 20% solids of colloidal silica (SiO_2) in water was mixed in a blender with submicron alumina powder (SM-8, Baikowski). The matrix contained 57 wt% of silica sol and 43 wt% of alumina powder. Several drops of nitric acid (about 0.1%) were added to the matrix to balance the pH. The matrix was then ball milled with alumina media for 4 hours before infiltrating into the fabric. The fabric was infiltrated by the same method as described in Example 1.

[0031] Those skilled in the art can now appreciate from the foregoing description that the broad teachings of the present invention can be implemented in a variety of forms. Therefore, while this invention has been described in connection with particular examples thereof, the true scope of the invention should not be so limited since other modifications will become apparent to the skilled practitioner upon study of the specification, examples and following claims.
